Cardiac metastasis of a hepatocellular carcinoma

Short breath, small vessels and big heart – an unusual suspect

Thierry Grandjean, Nicolas Brugger, Stéphane Cook, Gérard Baeriswyl

Summary

In most cases, dyspnoea, chest pain and negative T waves found on ECG represent myocardial ischaemia, pulmonary embolism, left ventricular hypertrophy or pericarditis. In some cases, the cause is unusual. We discuss here the case of a 76-year-old woman presenting with chest pain and dyspnoea as symptoms of a metastatic hepatocellular carcinoma located in her right ventricular septum and incidentally found on coronary angiography.

Key words: cardiac metastasis, right ventricular mass, neovessels, coronary angiography, dyspnea, chest pain.

Introduction

Metastatic cardiac tumours are rare (0.7%–3.5% of autopsy cases), but are more common in patients suffering from cancer (1%–14% of autopsy series) [1–3]. Spread to any part of the heart is possible, but involvement of the pericardium and epicardium is common, whereas spread to the myocardium and the endocardium is extremely atypical [1, 2]. In decreasing order of frequency, lung tumours, breast tumours and haematological malignancies are the most frequent cancers to have secondary cardiac metastases [1–3]. Melanoma

---

Figure: Panel A. The 12-lead ECG showing diffuse alterations of the repolarisation with inverted T waves (asterisk).
Panel B. The coronary angiogram of the right coronary artery (here LAO 30°) demonstrated a dense network of neovessels (tumor stain is delineated by arrows) tributaries from right marginal branches (RMAs) and septal branches (SB) from the posterior descending artery (PDA).
Panel C. Echocardiogram showing the tumour (arrows) in the right ventricle in parasternal long (PLAX-left) and short (PSAX-right) axis in 2D (upper) and its vascularisation with colour Doppler studies (lower).
Panel D. Chest CT showing the tumour (arrows) in the right ventricle.
has a unique propensity to metastasise to the heart. Metastases reach the heart by three potential paths: direct growth, through the bloodstream, or via the lymphatic system. Clinical presentations are diverse, varying from a serendipitous asymptomatic finding to constitutional symptoms, embolism or symptoms directly related to mass infiltration or obstruction.

Case report

A 76-year-old woman was referred for invasive coronary angiography because of new onset of exercise-induced chest pain and dyspnoea together with diffuse negative T wave inversion (asterisk) on a 12-lead ECG (fig. panel A). She had a history of hepatocellular carcinoma that was diagnosed 3 years before and was apparently cured with right hemihepatectomy, chemoembolisation, and systemic chemotherapy with sorafenib, a multikinase inhibitor. Recently, the patient had experienced a local recurrence and one solitary metastasis in the right inferior pulmonary lobe was discovered. Her quality of life was good and the oncologist in-charge predicted a 2-year life expectancy. Physical examination revealed right pleural effusion. The coronary angiogram, depicted in panel B of the figure, showed normal coronary arteries but a dense network of septal neo-vessels (arrows). Considering the likelihood of a myocardial mass, we next performed transthoracic echocardiography, which delineated a large vascularised mass in the right ventricular septal apex, with no outflow tract obstruction (fig. panel C). This cardiac mass was later demonstrated with chest computed tomography (panel D – arrows). Conservative treatment was considered.

Discussion

Cardiac metastases of hepatocellular carcinoma in the right ventricle are very rare [3, 4]. Hepatomas usually spread to the endocardium from the inferior vena cava system and that is probably what occurred in our patient. The prognosis is poor. Surgical resection has been performed to improve prognosis, or to control symptoms. Transcoronary chemoembolisation has been reported to effectively control symptoms [5]. As an alternative, although currently never reported, we considered metastasis embolisation by neo-vessel coiling, but refrained because of the risk of massive pulmonary tumour embolism during the process of necrosis.
